RANS AND LES INVESTIGATIONS OF VERTICAL FLOWS IN THE FUEL PASSAGES OF GAS-COOLED NUCLEAR REACTORS

Amir Keshmiri*, Mark A. Cotton, Yacine Addad, Stefano Rolfo and Flavien Billard

School of Mechanical, Aerospace and Civil Engineering (MACE), The University of Manchester, Manchester M60 1QD, U.K.

ABSTRACT
Coolant flows in the cores of current gas-cooled nuclear reactors consist of ascending vertical flows in a large number of parallel passages. Under post-trip conditions such heated turbulent flows may be significantly modified from the forced convection condition by the action of buoyancy, and the thermal-hydraulic regime is no longer one of pure forced convection. These modifications are primarily associated with changes to the turbulence structure, and indeed flow laminarization may occur. In the laminarization situation heat transfer rates may be as low as 40% of those in the corresponding forced convection case. The heat transfer performance of such ‘mixed’ convection flows is investigated here using a range of refined Reynolds-Averaged-Navier-Stokes (RANS) turbulence models. While all belong to the broad class of Eddy Viscosity Models (EVMs), the various RANS closures have different physical parameterizations and might therefore be expected to show different responses to externally-imposed conditions. Comparison is made against experimental and Direct Numerical Simulation (DNS) data. In addition, Large Eddy Simulation (LES) results have been generated as part of the study. Three different CFD codes have been employed in the work: 'CONVERT', 'STAR-CD', and 'Code_Saturne', which are respectively in-house, commercial, and industrial packages. It is found that the early EVM scheme of Launder and Sharma [1] is in the closest agreement with consistently-normalized DNS results for the ratio of mixed-to-forced convection Nusselt number ($\frac{Nu}{Nu_0}$). However, in relation to DNS and experimental data for forced convection Nusselt number, other models perform better than the Launder-Sharma scheme. The present investigation has revealed discrepancies between direct-simulation, experimental, and the current LES studies.

Keywords: ‘Eddy Viscosity Models’, ‘LES’, ‘Mixed Convection’, ‘RANS’.

1 INTRODUCTION
In the currently-operating UK fleet of Magnox and Advanced Gas-Cooled Reactor (AGR) stations, and also in proposed ‘Generation IV’ Very High Temperature Reactor (VHTR) designs, the core coolant flows vertically. The coolant in the existing stations is carbon dioxide and the principal flow ascends through the core; in VHTRs the coolant is helium and the flow descends. Density variations affect the flow, and heat transfer levels with respect to the corresponding forced convection flow at the same Reynolds and Prandtl numbers may be quantified in terms of a Nusselt number ratio, $\frac{Nu}{Nu_0}$. Under post-trip conditions, where the heat loading is relatively large in relation to the flow rate, such buoyancy effects have the potential to cause wholesale modifications to the turbulence structure. In the ascending flow case heat transfer levels may be either impaired (at moderate heat loadings), or enhanced (at very high heat loadings). In the case of descending flow, heat transfer levels are always enhanced. The complex phenomena associated with the mixed convection regime are discussed in the monograph of Petukhov and Polyakov [2] and the review paper of Jackson et al. [3].

Figure 1. Schematic Diagram of an Ascending Mixed Convection Flow

Attention in the present contribution is restricted to the ascending flow case, and the geometry, which consists of a long vertical pipe, is illustrated in Fig. 1. The thermal boundary is one of uniform wall heat flux.

Experimental studies of ascending turbulent mixed convection air flows include the works of Steiner [4], Carr et al. [5], Polyakov and Shindin [6], Vilemas et al. [7] and Shehata and McEligot [8]. In contrast, Parlatan et al. [9]
used water as the working fluid. Despite the primary focus of the present work being on gas-cooled reactors, comparison with the data of Parlatan et al. is reported below. (This is justified on the basis that a ‘buoyancy parameter’, defined in the Nomenclature, includes a Prandtl number dependence.)

With the advent of large-scale computing facilities, new mixed convection data have become available in the form of Direct Numerical Simulations. One of the earliest DNS studies was reported by Kasagi and Nishimura [10] who carried out computations on turbulent mixed convection between two vertical parallel plates maintained at different temperatures; in the present study comparison is made with the recent results of You et al. [11] who conducted a DNS study on turbulent mixed convection in a heated vertical pipe for conditions of constant properties with buoyancy accounted for using the Boussinesq approximation. This feature of their computations enables the effects of buoyancy to be studied in isolation from other influences associated with the non-uniformity of fluid properties and flow acceleration.

Amongst other works, turbulence model results for mixed convection flows may be found in Abdelmeguid and Spalding [12], Cotton and Jackson [13], Kirwin [14] and Kim et al. [15]. The latter three works examined ‘low-Reynolds-number’ EVMs in which viscous terms are defined in the Nomenclature, includes a Prandtl number (This is justified on the basis that a ‘buoyancy parameter’, defined in the Nomenclature, includes a Prandtl number dependence.)

2 COMPUTATIONAL FRAMEWORKS

2.1 Mean Flow Equations

The mean flow equations are written in the ‘thin shear’, or ‘boundary layer’, and Boussinesq approximations. Thus, in Cartesian tensor notation (where $U_j$ represents a mean velocity component), the mean flow conservation equations are as follows:

**Continuity:**

\[ \frac{\partial U_j}{\partial x_j} = 0 \]  

(1)

**Momentum:**

\[ \rho \frac{D U_j}{D t} = -\frac{\partial p}{\partial x_j} + \frac{\partial}{\partial x_j} \left( \mu + \mu_t \right) \frac{\partial U_j}{\partial x_j} + \rho g_i [1 - \beta (T - T_0)] \]  

(2)

where: $g_i = \begin{cases} -g & \text{for ascending flow} \\ +g & \text{for descending flow} \end{cases}$

**Energy:**

\[ \rho \frac{D T}{D t} = \frac{\partial}{\partial x_j} \left[ \left( \frac{\mu + \mu_t}{\sigma_r} \right) \frac{\partial T}{\partial x_j} \right] \]  

(4)

where, following standard modelling practice, e.g. [1], the turbulent Prandtl number is set to a constant value, $\sigma_t = 0.9$.

2.2 Refined Eddy-Viscosity Models implemented in an In-House Code, ‘CONVERT’

‘CONVERT’ (for Convection in Vertical Tubes) was originally advanced by Cotton [16] as a modification of the finite volume/finite difference code ‘PASSABLE’ developed by Leschziner [17]. CONVERT differs from PASSABLE in its use of the ‘exact’ pressure correction scheme of Raithby and Schneider [18]; the years since the appearance of [16] have seen many refinements made to CONVERT, for example Kirwin [14] extended the code to have full variable properties capabilities (i.e. the Boussinesq approximation was not adopted and therefore more extreme temperature variations could be examined). Here, however, the program is used in its original form where the mean flow governing equations are given by Eqs. (1)-(4).

The radial mesh comprises 100 control volumes and a double-expansion technique is employed to ensure good resolution of the near-wall flow (the wall-adjacent node is typically located at $y^+ = 0.5$, and approximately half the nodes are positioned between the wall and $y^+ = 60$). The governing equations are parabolic and small steps are taken in the axial direction to advance the solution. At-station iteration is applied to ensure a converged solution at each axial location. A number of carefully-conducted sensitivity tests have been applied here and in previous studies to ensure the numerical reliability of the results presented below.

**Figure 2. CONVERT Solution Sequence**

Figure 2 shows the solution technique: first, an initial isothermal run (‘RUN 1’) is made in which the dynamic field is allowed to develop from approximate initial profiles to a fully-developed state as determined by the particular turbulence model in use. In the present work, RUN 1 was typically set to 50D. Next, a mixed convection run (RUN 2) reads the fully-developed mean flow and turbulence profiles from RUN 1 at $x = 0$. A uniform wall heat flux is applied and the buoyancy force term is activated in Eq. (2). In those cases where it is required that the mixed convection run should itself reach a hydrodynamically and thermally fully-developed state, RUN 2 is extended 500 diameters downstream of $x = 0$, although, as will be seen later, in the case of one particular EVM the domain had to be restricted to 50D because of convergence difficulties.
Three EVMs have been examined using CONVERT:

1) The Launder and Sharma model [1], hereafter the ‘LS model’, in which the eddy, or turbulent, viscosity is formulated in terms of \( k \), the turbulent kinetic energy, and \( \varepsilon \), a modified expression for the rate of viscous dissipation of \( k \). Transport equations are carried for \( k \) and \( \varepsilon \), and, as noted previously, ‘damping’ (with respect to a high-Reynolds-number asymptotic model form) is achieved primarily in terms of a turbulent Reynolds number.

2) A three-equation scheme due to Cotton and Ismael [19], the ‘CI model’, in which an additional transport equation for a ‘strain parameter’, \( S \) is included. Damping is principally in terms of \( S \), with only limited dependence on \( Re_c \).

3) The Craft-Launder-Suga non-linear EVM [20], the ‘Suga model’. This closure achieves damping in a manner similar to that of the CI model, although there is no third transport equation in the Suga scheme. While the model constitutive equation incorporates quadratic and cubic functions of the mean strain rate and vorticity tensors, these terms are not significant in flows subject to simple shear. The Suga model is also implemented in STAR-CD [21] (see Section 2.4 below).

More detailed descriptions of the three turbulence models may be found in the original papers and Keshmiri et al. [22].

2.3 Development of the ‘Manchester \( \nu^2-f \) Model’

Using ‘Code_Saturne’

‘Code_Saturne’ is a general purpose industrial CFD code developed by Electricité de France (EDF). The program is applicable to three-dimensional steady and unsteady single phase flows. A finite volume approach is adopted and variables are stored using a fully collocated arrangement [23].

![Figure 3. The Mesh used in Code_Saturne and STAR-CD](image)

The mesh used for the present ‘Code_Saturne’ and STAR-CD computations is shown in Fig. 3. The domain consists of a 2-degree sector of the pipe cross-section. Periodic boundary conditions are applied in the streamwise (\( x \)) direction, while symmetry boundary conditions are applied at the two azimuthal (\( \theta \)) faces. The face at \( r = R \) represents the pipe wall. In principle, only one cell is necessary in the streamwise direction, however, five are used to promote convergence. There are 120 cells in the radial direction and the wall-adjacent cell is positioned at \( 0.15 < y^+ < 0.2 \).

Two eddy viscosity models are investigated in the ‘Code_Saturne’ computations:

1) The first scheme is the 2-equation \( k-\omega-SST \) model of Menter [24] (where ‘SST’ denotes Shear Stress Transport). The model is a development of Wilcox’s \( k-\omega \) EVM [25] in which \( \omega \), the large-scale turbulence frequency, is selected in preference to \( \varepsilon \) as the subject of the second transport equation. (The model of [24] is also implemented in STAR-CD, and direct comparison of the two codes is reported in Section 3.)

2) The second model is the Manchester \( \nu^2-f \) scheme, which, in view of its recent development, is now discussed in some detail.

The original \( \nu^2-f \) model of Durbin [26] has as its starting point two-equation \( k-\nu \) EVMs of the type introduced above, e.g. the LS model. However, a third transport equation is included for \( \nu^2 \), one of the three Reynolds normal stresses (\( \nu \) is the wall-normal component of the fluctuating velocity vector). \( \nu^2 \) is used in a revised definition of turbulent viscosity given by the following equation:

\[
\nu_t = \frac{C_p \nu^2 T_f}{\min(k, \varepsilon, \sqrt{\nu^2/\varepsilon})}. \tag{5}
\]

The \( \nu^2 \)-equation includes a redistributive source term, \( f \) which represents a modelled form of the pressure-strain correlation. An elliptic equation is used in the determination of the source term, a feature that allows cognizance to be taken of non-local effects. Unfortunately, incorporation of the original scheme in an industrial segregated solver (where the governing equations are solved sequentially) may give rise to numerical problems related to the ‘stiffness’ of the equation set, and it is this consideration that has led to the development of a number of alternative approaches, including the current revised formulation.

Lien and Durbin [27] subsequently developed a ‘code friendly’ version of the scheme which sought to overcome the numerical issues alluded to above. However, a source term in the \( f \)-equation was neglected in the Lien-Durbin formulation, an omission that had the effect of causing the revised scheme to return results that were significantly different from those of the original model. Two later attempts were made to produce a form of the \( \nu^2-f \) closure that would be suitable for use in industrial segregated codes (Laurence et al. [28]; Hanjalić et al. [29]). The models of [28] and [29] solved a transport equation for a dimensionless variable \( \phi = \sqrt{\nu^2/k} \) in place of \( \nu^2 \). The terms neglected in the \( \phi \)-based variants were less significant than those of [27]; however, numerical problems persisted and the models were prone to be unstable, particularly in near-wall regions.

The refinement of the \( \nu^2-f \) model proposed here uses an ‘elliptic blending’ approach (Manceau [30]) in order to
strengthen the coupling between \( \varphi \) and \( f \). Thus, an elliptic equation is solved for a ‘blending parameter’, \( \alpha \):

\[
L \nabla^2 \alpha - \alpha = -1
\]

(6)

where \( L = C_L \max\left( k^{3/2} / \varepsilon, C_\eta (v^3 / \varepsilon)^{1/4} \right) \).

The blending parameter varies the weighting between a near-wall sub-model (Eq. (7), below) and a homogeneous sub-model (Eq. (8)) that appear in the \( \varphi \)-equation (Eq. (9)):

\[
\begin{align*}
    f_{\text{wall}} &= -\frac{\varphi}{k} \\
    f_{\text{hom}} &= -\frac{1}{T_i} (C_j + C_2 \frac{P}{\varepsilon} - 1)(\varphi - \frac{2}{3}) \\
    \frac{D\varphi}{Dt} &= \alpha^2 f_{\text{hom}} + (1 - \alpha^2) f_{\text{wall}} - \frac{P_k}{k} \varphi + \frac{2}{k} \left( \frac{\nu_j}{\sigma_j} \right) \frac{\partial}{\partial x_j} \left[ \left( \nu + \frac{\nu_j}{\sigma_j} \right) \frac{\partial \varphi}{\partial x_j} \right]
\end{align*}
\]

(7) \hspace{1cm} (8) \hspace{1cm} (9)

The wall boundary condition applied to Eq. (6) is \( \alpha = 0 \), an aspect of the current proposal that greatly alleviates the problems experienced by other workers in relation to the stiffness of the equation set. The transport equations for turbulent kinetic energy and its dissipation rate read as follows:

\[
\begin{align*}
    \frac{D\rho k}{Dt} &= \rho \frac{C_{\mu}}{T_i} \left( P_k - \rho e + \frac{\partial}{\partial x_j} \left[ \left( \mu + \frac{\mu_j}{\sigma_j} \right) \frac{\partial k}{\partial x_j} \right] \right) \\
    \frac{D\rho e}{Dt} &= \rho \frac{C_{\mu}}{T_i} (P_k - C_{\mu} \varepsilon) + \frac{\partial}{\partial x_j} \left[ \left( \mu + \frac{\mu_j}{\sigma_j} \right) \frac{\partial e}{\partial x_j} \right]
\end{align*}
\]

(10) \hspace{1cm} (11)

2.4 Validation Tests using ‘STAR-CD’

STAR-CD [21] is an unstructured code and, in common with CONVERT and Code_Saturne, solves the governing equations using a finite volume approach. It is a powerful package in the sense that it performs all the necessary operations for a flow problem, including pre-processing, processing, and post-processing. It also allows the user to undertake analysis of a wide range of different flows: transient, multi-phase, and compressible, as well as combinations of these. It is also capable of carrying out simulations which may involve heat and mass transfer and chemical reaction. STAR-CD offers a wide range of RANS models in addition to having LES capabilities.

As part of the present work, STAR-CD was used to generate results using the following four turbulence models:

1) A low-Reynolds-number \( k-\varepsilon \) model due to Lien et al. [31], termed the ‘Standard Low-Reynolds-Number Model’ in the STAR-CD documentation [21]. The formulation is similar to the LS model, however, the \( \varepsilon \)-equation is cast in a slightly different form, in part to improve the convergence properties of the model.

2) The ‘Suga model’ [20]. As noted above, this has the same form as the model implemented in CONVERT. It was found, however, that STAR-CD computations with the Suga model were highly unstable and it proved impossible to generate reliably converged simulations. In consequence, Section 3 does not include any results obtained using the STAR-CD/Suga model combination.

3) Menter’s \( k-\omega-\text{SST} \) model [24]. This model is the same as that used in Code_Saturne.

4) The \( \nabla^2 - f \) model of Lien and Durbin [27] (discussed above in connection with the development of the present Manchester \( \nabla^2 - f \) scheme). This model is also available in Code_Saturne.

2.5 Large Eddy Simulation

In a departure from the various Reynolds-averaged turbulence closures described above, the final set of computations undertaken in the present work consist of Large Eddy Simulations in which there is no modelling of the larger, energy-containing, turbulence structures, but where the smaller dissipative eddies are represented using a ‘Sub-Grid-Scale’ model. The commercial code STAR-CD (version 4.02) has been used for these computations and the small scales are modelled using the classical Smagorinsky/Lilly model. The model constant, \( C_p \), is taken to be equal to 0.047 with the grid filter, \( \Delta \), defined to be twice the cube root of the cell volume in the sub-grid viscosity expression:

\[
\mu_f = \left(C_f \Delta^2 \right)^{1/2} \]

(12)

To account for near-wall effects, Lilly [32] suggested expressing the sub-grid filter as:

\[
\Delta = \min(\kappa \gamma, \Delta)
\]

(13)

where \( \kappa = 0.42 \) and \( y \) is the nearest distance from the wall. The turbulent Prandtl number is fixed at 0.9.

Details of the physical aspects of the LES procedures employed and the calibration of the sub-grid model are presented by Addad [33]. The current LES grid represents a full pipe section (and not a segment as in Fig. 3). Mirroring the DNS computations of You et al. [11], the current domain is made long in the streamwise direction (=30R) in order to avoid the generation of spurious flow-oriented spatial correlations. The resolution of the grid at the wall is \( \Delta x^+ = 1.0 \), \( R \Delta \theta^+ = 6.3 \), and \( \Delta z^+ = 18.0 \), while the resolution of the
DNS grid used by You et al. was $\Delta x = 0.2$, $Ra\phi^+ = 8.8$ and $\Delta x^+ = 10.5$. Using the same LES grid, the present authors have performed 7 runs for various values of the buoyancy parameter, $Bo$.

3 RESULTS AND DISCUSSION

Results are presented in two main sections: in the first of these, Nusselt number impairment or enhancement with respect to the Nusselt number for pure forced convection, $Nu_0$, is examined. Fully-developed $Nu/Nu_0$ is plotted against a ‘buoyancy parameter’, $Bo$ which was first developed by Hall and Jackson [34]. In the present work $Bo$ is defined as:

$$Bo = 8 \times 10^4 \frac{Gr}{(/Re^{1.425} Pr^{0.8})}$$  (14)

This form was advanced by Jackson et al. [3]. Present EVM and LES computations are compared against several sets of experimental data and the DNS results of You et al. [11].

The second group of calculations provides greater detail of thermal-hydraulic development by plotting $Nu$ vs. $\alpha/D$. However, it is the case that fewer models are employed; and comparison is made with the experimental data of Polyakov and Shindin [6].

3.1 Computations of Heat Transfer Impairment and Enhancement

Since forced convection Nusselt number is to supply the normalizing parameter in the presentation of heat transfer impairment/enhancement effects, it is appropriate first to assess model performance in the computation of buoyancy-free pipe flows. All runs are performed for $Re=5300$ (or $Re_f=180$) and $Pr=0.71$, the values selected by You et al. [11] (Note, however, that the presentation below of mixed convection results in terms of the buoyancy parameter of Eq. (14) does allow cautious extrapolation to other flow conditions.)

The results of this initial assessment are summarized in Table 2 and Fig. 4 which show values of local friction coefficient and Nusselt number computed using the eight turbulence model/code combinations and single LES approach under current investigation. The first points on the left of Fig. 4 and the horizontal broken lines represent the DNS results of You et al. It is immediately apparent that, even for this simple ‘baseline’ case, there is significant disparity between the various schemes.

It is noted that the long-established Launder-Sharma model somewhat under-predicts the DNS values of $Nu_0$ and $c_{f0}$. A particularly large discrepancy in the value of $Nu_0$ is returned by the STAR-CD $k-\omega$–SST model (+19.7%), while the ‘Standard’ $k-\varepsilon$ formulation implemented in STAR-CD produces too low a value of $c_{f0}$ (-17.8%).

Naturally, an under- or over-prediction of $Nu_0$ will affect the absolute level of mixed convection deduced from values of $Nu/Nu_0$ to be examined next. The DNS value of $Nu_0$ is itself 7% lower than that found from the experiments of Polyakov and Shindin [6] (discussed further in Section 3.2 below).

Also shown in Fig. 5 are the data of Steiner [4], Carr et al. [5] and Parlatan et al. [9]. While these data were obtained for values of $Re$, $Pr$, and $Gr$ different from those of You et al., all are cast in terms of $Bo$ (which, in its nature, is an approximate quantification of buoyancy influence, [34, 31]). Another factor affecting the experimental data, but not accounted for in the DNS of You et al. or the present simulations, relates to variable property (principally viscosity) influences; this point is considered in more detail in Section 3.2, below. The final elements completing Fig. 5 are $Nu/Nu_0$ vs. $Bo$ distributions computed using the various turbulence models and LES of the present study (Following
You et al., Re and Pr were unchanged from the forced convection tests). Where available, all sets of data and the present computations are normalized using the corresponding \( \text{Nu}_0 \) value of that particular test case. (However, note that some of the physical experiments represented in Fig. 5 did not report forced convection Nusselt numbers and in these cases the present authors have been obliged to use an established heat transfer correlation to normalize the mixed convection Nusselt numbers of the experiments.)

The most striking picture to emerge from Fig. 5 is the abrupt and dramatic reduction in heat transfer levels occurring at around \( 0.15 < \text{Bo} < 0.25 \). DNS Case C (\( \text{Bo} = 0.18 \)) is representative of this laminarized state in which heat transfer levels are only approximately \( 1/10 \) of those found in forced convection under otherwise identical conditions. The formulation in closest agreement with the three DNS data points is the LS model (as implemented in CONVERT). Other models that perform well are the Manchester \( \nabla^2 f \) scheme (Code_Saturne) and the Lien and Durbin \( \nabla^2 f \) model (STAR-CD), although these two schemes are not as close to the DNS point at the lowest level of buoyancy influence (Case B; \( \text{Bo} = 0.13 \)). The Large Eddy Simulations (STAR-CD) indicate that significant heat transfer impairment occurs at a lower value of \( \text{Bo} \), and interestingly these results, at least at lower levels of buoyancy influence, are in good agreement with the water data of Parlatan et al. when both the LES and data are presented in terms of \( \text{Bo} \).

The CI model (CONVERT) returns an unduly late onset of impairment. The Suga model (also coded in CONVERT) shows a considerable delay in the onset of heat transfer impairment and also significantly under-predicts the extent of impairment (these results are for \( x/D = 50 \) because, for cases with relatively high \( \text{Bo} \), converged solutions could not be obtained at locations further downstream). The \( k-\omega\text{-SST} \) model (STAR-CD and Code_Saturne) performs particularly poorly, but there is at least quite close agreement between the two codes. Finally in relation to the turbulence models, it is observed that the ‘Standard’ \( k-\epsilon \) model (STAR-CD) returns somewhat different results from the LS scheme, mainly for lower values of \( \text{Bo} \). Examining the experimental data for the ‘Recovery’ region (\( \text{Bo} \geq 0.2 \)), a general observation might be made that there is considerable scatter in the measurements, a feature that may be due in part to variable property effects.

### 3.2 Nusselt Number Development - The Experiments of Polyakov and Shindin

Heat transfer development is examined next and comparison is made with the experimental data of Polyakov and Shindin.
Figure 6. Nusselt Number Development. (a)-(e): Polyakov and Shindin [6] Runs 1-5 (Table 4)
CONVERT is used to run the LS, CI, and Suga models. Conditions at the start of heating are given in Table 4 together with the bulk temperature rise along the test section. In Run 5 $\Delta T_b$ is sufficiently large to invalidate the Boussinesq approximation, see for example Gray and Giorgini [35]. Comparison with Run 5 is included only for completeness since for these conditions a full variable properties formulation (e.g. Kirwin [14]) should be adopted.

Figure 6 shows plots of Nusselt number against axial position arranged in order of increasing buoyancy influence. Forced convection flow is represented by Fig. 6(a) from which it is seen that the CI model is closest to the measurements, while the Suga and LS models return lower values of $Nu$. The average value of forced convection Nusselt number obtained from the data of Polyakov and Shindin is $Nu_0 = 19.0$ (for $30 < x/D < 65$). Now, Polyakov and Shindin’s experiments were conducted for $Re = 5100$ (cf. $Re = 5300$ in the DNS of You et al. [11]). If $Nu_0$ is taken to vary as $Re^{0.8}$, the experimental result can be scaled to yield $Nu_0 = 19.0 \times (5300/5100)^{0.8} = 19.6$ at the higher Reynolds number. (The scaled value of $Nu_0$ appears in Table 2 and Fig. 4, above.) The discrepancy between the scaled experimental value and the value of $Nu_0$ quoted by You et al. ($Nu_0 = 18.3$) may raise some question over the accuracy of the DNS.

Figures 6(b) and (c) are for values of $Bo$ associated respectively with early-onset mixed convection and heat transfer recovery. The LS model is closest to the data of Fig. 6(b), and, while no model accurately captures the development history of Fig. 6(c), the LS scheme is in best agreement with the measurements made in the downstream region. Further into the recovery region, Fig. 6(d) shows that the LS model performs better than the other two schemes. As indicated previously, variable property effects in Run 5 (Fig. 6(e)) render the Boussinesq approximation inapplicable, and it would be inadvisable to draw any firm conclusions from these results.

4 CONCLUDING REMARKS

The present work has examined a number of eddy-viscosity turbulence models against experimental and DNS data for ascending buoyancy-influenced ‘mixed’ convection. The various turbulence closures adopt a range of different strategies to account for departures from the ‘universality’ of flow behaviour that is associated with fully-developed forced convection conditions. Thus, for example, ‘damping’ in the constitutive stress/strain may be made to depend on a local turbulent Reynolds number (the Launder-Sharma model [1]), a dimensionless strain parameter (the Cotton-Ismael model [19]), or the wall-normal Reynolds stress (the Lien-Durbin [27] and ‘Manchester’ $\nu \cdot f$ schemes). Large Eddy Simulation results have also been generated as part of the project.

Initial comparison of the present turbulence model and LES results with forced convection data generated by You et al. [11] produced a somewhat inconsistent picture, whereby a given model might return a reasonably accurate value for Nusselt number, but not local friction coefficient (or vice-versa). The situation is compounded further by the observation that the DNS value for $Nu_0$ is approximately 7% lower than the experimental measurement of Polyakov and Shindin [6].

The Launder-Sharma turbulence closure was found to be in the closest agreement with the DNS data of You et al. for the ratio of mixed-to-forced convection Nusselt number ($Nu/Nu_0$), clearly reproducing the large-scale impairment of heat transfer associated with ascending mixed convection flows. The two $\nu \cdot f$ variants produced the next most accurate results. There is some difference between the current LES results and the DNS data, a matter that is to receive further attention in the course of the research programme (in particular the present authors intend to carry out more refined LES runs). In-house, industrial, and commercial codes (respectively CONVERT [16], Code_Saturne [23], and STAR-CD [21]) were used in this part of the study. Satisfactory agreement between Code_Saturne and STAR-CD was obtained when using the $k-\omega$–SST model of Menter [24], although the scheme performed poorly in comparison with data.

The Launder-Sharma, Cotton-Ismael and Suga [20] models were next evaluated in comparison with the data of Polyakov and Shindin [6] for developing forced and mixed convection flows. The Cotton-Ismael scheme was in the best agreement with the forced convection case; however, the Launder-Sharma model was found to be superior in the computation of mixed convection flows. Thus, it does not appear at present that any single turbulence model can be recommended unequivocally for the calculation of the broad flow class under present consideration.

Finally, it must be noted that attention in the present paper has been restricted to the practically important question of heat transfer performance. A more complete assessment of a turbulence model requires an examination of mean flow and turbulence profiles and this will be done in a companion work [22].

ACKNOWLEDGEMENTS

The authors would like to thank Professor D. R. Laurence for his input to the present project.

This work was carried out as part of the ‘Towards a Sustainable Energy Economy’ (TSEC) program ‘Keeping the Nuclear Option Open’ (KNOO) and as such we are grateful to the UK Engineering and Physical Sciences Research Council for funding under grant EP/C549465/1.
**NOMENCLATURE**

- $B_o$: Buoyancy parameter, $8 \times 10^4 Gr/(Re^{1.425} Pr^{0.8})$
- $c_f$: Local friction coefficient
- $C_s$: The constant for Smagorinsky model
- $D$: Pipe diameter
- $Gr$: Grashof number, $\beta g D^4 q / (\nu^2)$
- $k$: Turbulent kinetic energy, $u_i^2 / 2$
- $L$: Length scale
- $Nu$: Nusselt number, $\dot{q}D / (\lambda(T_w - T_b))$
- $p$: Pressure
- $P_k$: Rate of shear production of $k$
- $Pr$: Prandtl number, $c_p \mu / \lambda$
- $\dot{q}$: Wall heat flux
- $q^+$: Heat loading parameter, $\dot{q}/(\rho \nu U_b c_p T_b)$
- $r, x, \theta$: Cylindrical polar coordinates
- $R$: Pipe radius, $D/2$
- $Re$: Reynolds number, $U_b D / \nu$
- $Re_t$: Turbulent Reynolds number, $k^2 / (\nu \varepsilon)$
- $Re_e$: Reynolds number based on frictional velocity, $U_b D / \nu$
- $\bar{s}$: The resolved rate of strain
- $t$: Time
- $T$: Temperature
- $T_i$: Turbulent timescale
- $U_i, u_i$: Mean, fluctuating velocity components in Cartesian tensor notation
- $U_t$: Friction velocity, $(\tau_w / \rho)^{1/2}$
- $x, y$: Streamwise and wall-normal coordinates
- $y^+$: Dimensionless distance from the wall, $yU_t / \nu$

**Greek Symbols**

- $\beta$: Coefficient of volumetric expansion
- $\Delta$: The filter width for the LES approach
- $\varepsilon$: Dissipation rate of $k$
- $\varepsilon^+$: Modified dissipation rate, $\varepsilon - 2\nu (\partial k^{1/2} / \partial x_i)^2$
- $\kappa$: Von Karman constant
- $\lambda$: Thermal conductivity
- $\mu$: Dynamic viscosity
- $\mu_t$: The turbulent viscosity or sub-grid viscosity in LES
- $\nu$: Kinematic viscosity, $\mu / \rho$
- $\rho$: Density
- $\tau_w$: Wall shear stress

**Subscripts**

- $b$: Bulk
- $t$: Turbulent
- $w$: Wall
- $\theta$: Forced convection

Additional symbols are defined in the text.
